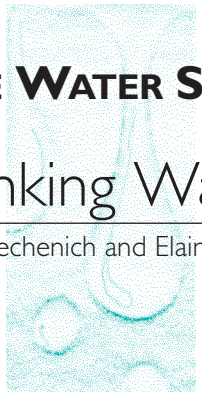
G3558-4

HOME WATER SAFETY

Interpreting Drinking Water Test Results

by Chris Mechenich and Elaine Andrews



This fact sheet is part of a series designed to help you determine the quality of your home drinking water and to show you techniques available for improving it. To make the best use of these publications, include them in a household file containing well information and water test results.

Other fact sheets in the series are:

G3558-1 Keeping Your Home Water Supply Safe

G3558-2 Evaluating the Condition of Your Private Water Supply

G3558-3 Evaluating the Condition of Your Public Water Supply

G3558-5 Choosing a Water Treatment Device

Extension bulletin G3399 *Maintaining Your Home Well Water System*, can be used with these publications.

This series was developed by the University of Wisconsin Cooperative Extension in cooperation with the Wisconsin Department of Natural Resources and the Wisconsin Department of Industry, Labor and Human Relations.

Rotten-egg smells, red-brown stains on plumbing fixtures, bathtub rings—all these are unpleasant signs of water quality problems, but usually not of harmful contaminants in the water. Contaminants that may threaten our health are usually not discernible by the senses. Drinking water can contain nitrate, bacteria, and pesticides at levels which cannot be tasted or smelled, but which can be hazardous to health.

If your drinking water comes from a private well, you should test your water once a year even if you do not observe any smells, stains or changes in water quality. Only analysis by a certified laboratory can determine if the water is free of harmful contaminants. This publication provides information about how to interpret the laboratory results for a basic set of tests that are recommended for all private wells.

The tests described in this publication are also conducted on public water supplies. If you are using water from a public water utility, consider having the water tested if your home plumbing system contains lead pipes or lead solder, if you are installing a water treatment device, or if you have concerns about the water. See fact sheet G3558-3 *Evaluating the Condition of Your Public Water Supply*, for more information.

The Initial Set of Water Tests

Anyone buying a new home with a private well, installing a new well or simply having their well water tested for the first time should run the basic set of tests described here. These tests give a good overall picture of current water quality, indicate possible problems, and provide a "baseline" for comparing future test results. Each test is described in more detail in this publication.

Always have a certified laboratory conduct the tests. Labs certified by the Department of Natural Resources must meet standards for accuracy and quality. A list of certified labs is available from county Extension offices and district Department of Natural Resources (DNR) offices.

What is a Part per Million?

Laboratory equipment can measure contaminants in water at extremely low levels, such as parts per million (ppm) or even parts per billion (ppb). For example, one part per **million** can be imagined as one red marble mixed in with 999,999 blue marbles, one inch in sixteen miles, or a minute in the space of two years. One part per **billion** is the same as two croutons in a five hundred pound salad, or eight drops of water in an Olympic-sized swimming pool.[1] Although such small numbers may seem quite insignificant, even one part per billion or less of certain chemicals has been found to cause adverse health effects.

[1]These creative part-per-million and part-per-billion examples are from the WaterTest Corporation, New London, NH.

Tests to Identify Contaminants that Harm Health

BACTERIA. Coliform bacteria are usually not harmful, but indicate the possible presence of disease-causing bacteria from human or animal waste.

NITRATE. A form of nitrogen that can dangerously reduce the amount of oxygen in the blood of infants under six months old. Nitrate, introduced into groundwater by humans, is a common contaminant, and often indicates the presence of other contaminants.

LEAD. Lead can be leached into water from lead pipes or solder and can represent a significant health threat.

Tests to Determine Overall Water Quality

ALKALINITY. Measurement needed to determine corrosivity.

CHLORIDE. High concentrations often indicate contamination by a septic system, fertilizer, a landfill or road salt.

CONDUCTIVITY. Measures the ability of water to conduct an electrical current; can be used to signal the presence of contaminants.

CORROSIVITY INDEX. A combination of several tests that indicates the tendency for water to corrode plumbing, or for lime deposits to form in pipes.

HARDNESS. Helps determine the need for water softening; also influences corrosivity.

pH. Indicates water's acidity and helps determine if water will corrode plumbing.

After running the initial set of tests, well users should continue to test for bacteria once a year. It's also a good idea to test for nitrate annually for several years. If nitrate levels are consistently low, nitrate tests are not necessary every year. However, a nitrate test should always be conducted if an infant is drinking the water.

A Note on Drinking Water Standards

Public water supplies must meet numerical water quality standards set by state and federal governments and enforced by the Wisconsin DNR. Water from private wells does not have to meet these standards. However, users of private well water should at least be aware of the broad range of contaminants that may be found in well water and that concern public health officials.

Primary standards provide health limits for 60 contaminants as of January, 1991. The list continues to grow and may include up to 85 contaminants by 1993. It includes 8 inorganic compounds, such as arsenic, copper and lead; 17 pesticides, such as aldicarb and chlordane; 10 volatile organic chemicals such as benzene and trichloroethylene; PCBs; 3 microbial pathogens; and 5 radioactive

elements. Secondary standards provide aesthetic limits for 13 contaminants, such as iron, zinc, color and odor. The sources and maximum contaminant levels (MCL) for these substances are described in the publication *Private Drinking Water Supplies* listed in the resource section of this fact sheet.

Testing private well water supplies for all these contaminants would be expensive and is not recommended unless your well is too close to a known source of contamination.

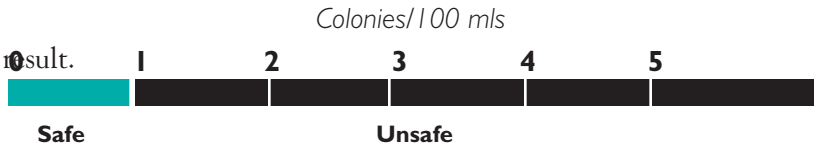
The Initial Water Tests: What the Results Mean

The initial set of water tests can provide a good overview of your well water quality if you know how to interpret the results. The information below provides a starting point for evaluating your water quality.

Note that water test results are usually presented in milligrams per liter (mg/1) or micrograms per liter (µg/l). For example, a water test might indicate that the water contains 6 mg/l nitrate, meaning that a liter of water contains an average concentration of 6 milligrams of nitrate. Note also that one mg/l is equivalent to one part per million (ppm). One µg/l equals one part per billion (ppb).

Coliform Bacteria

Coliform bacteria are microorganisms found in surface water, soil and in the feces of humans and animals. They do not usually cause disease. However, their presence indicates that wastes may be contaminating the water and means that pathogenic (disease-causing) organisms could be present. If human or animal wastes are contaminating the water, gastrointestinal diseases or hepatitis may



ACCEPTABLE RESULTS: 0 coliform/100 milliliters (ml) of water (also called 0/5). If you have 1 or more coliform colonies/100 milliliters of water, you should resample. If a second test shows coliform, take corrective action.

CORRECTIVE ACTIONS: Coliform bacteria in groundwater indicate that contaminated surface water is entering groundwater without the filtering effect that soils usually provide. In areas where the bedrock is fractured and close to the surface, contaminated surface water can naturally find its way into the groundwater. More often, detection of coliform bacteria in well water is an indication that contaminated

surface water is entering a well because of defects in well construction or maintenance.

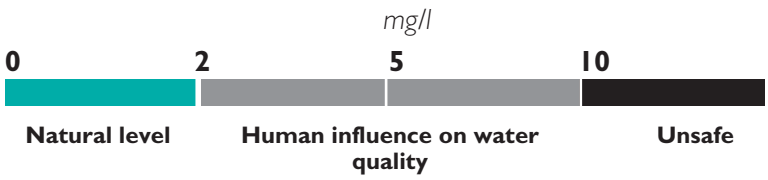
If coliform bacteria are detected in the water sample, have another sample tested. Carefully follow the sampling steps suggested by the laboratory to ensure that your sampling procedure itself is not contaminating the water. If the second test shows bacterial contamination, check the well for defects. Some defects are easily viewed; others might require excavating around the well. Follow this checklist as you look for obvious defects:

- ✓ Is the cap or seal on tightly? Is the well vented? The well cap should be tight fitting to keep out surface water and vermin. The screened vent that allows air to enter the well must be securely connected to the cap or seal.
- ✓ Is all wiring in conduit (tubing that connects the well with the electrical box)?
- ✓ Is the casing at least 12 inches above the ground? (The casing is the steel or plastic pipe installed in the bore hole during construction.) Also, if there are visible holes or cracks in the casing, or if you can move it, there might be a problem.
- ✓ Is the well in a pit or basement? If so, it may not meet state requirements and might be unsafe.

After correcting visible defects, disinfect the well with chlorine bleach and have another sample tested. See DNR publication *Bacteriological Contamination of Drinking Water* and fact sheet G3558-2 *Evaluating the Condition of Your Private Water Supply* for more information.

Nitrate

Nitrate nitrogen is a commonly used lawn and agricultural fertilizer. It is also a chemical formed in the decomposition of waste materials. If infants under six months of age drink water (or formula made with water) that contains more than 10 ppm nitrate-nitrogen, they are susceptible to methemoglobinemia, a disease which interferes with oxygen transport in the blood. High nitrate levels also suggest that other contaminants may be present. The natural level of nitrate in Wisconsin's groundwater is less than 2 mg/l. *Nitrite* is an unstable form of nitrogen which may be found in small amounts along with nitrate. Sometimes results of nitrate and nitrite are reported together.



ACCEPTABLE RESULTS: Labs report nitrate results either as nitrate-nitrogen or as nitrate. When reported as nitrate nitrogen (NO_3-N) or nitrate and nitrite nitrogen (NO_2 + NO_3-N) the acceptable level is less than 10 mg/l (less than 2 mg/l is preferred). When reported simply as nitrate (NO_3), the acceptable level is less than 45 mg/l.

SOURCES: Fertilizer, septic system effluent, animal wastes, and landfills can all contribute to elevated nitrate levels. In most cases, elevated nitrate levels indicate general contamination of the aquifer (water-bearing formation) at that depth.

CORRECTIVE ACTIONS:

- ✓ Deepen or replace the well. Nitrate is more commonly found in shallow wells. Drilling to a deeper part of the aquifer might help reduce nitrate levels.
- ✓ Eliminate contamination sources. If the source of the nitrate can be identified (such as a nearby barnyard or septic system) the best solution might be to clean up or remove the contamination source. However, it could take years for the nitrate to return to safe levels in the well.
- ✓ Carry or buy water, especially for infants.
- ✓ Treat the water. Some home water treatment devices can remove nitrate from drinking water. See fact sheet G3558-5 *Choosing a Water Treatment Device* for more information.

Lead

Lead is a toxic metal which can damage the brain, kidneys, nervous system, red blood cells and reproductive system. It is a greater hazard to young children, infants and fetuses than to adults. High concentrations of lead are rare in Wisconsin's groundwater supplies. However, lead is still a significant health hazard in drinking water, because most homes constructed before 1985 have copper water pipes soldered together with a solder that contains lead. Homes with soft water are at greatest risk of lead leaching from the solder

into the drinking water.

ACCEPTABLE RESULTS: less than 15 µg/l (parts per billion) lead.

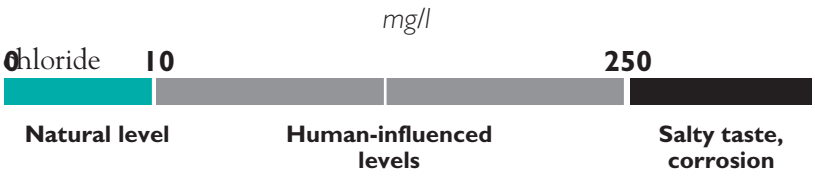
SOURCES: lead solder in copper pipes, lead pipes or service connections.

CORRECTIVE ACTIONS :

- ✓ Before using water for cooking or drinking, flush the cold water faucet by allowing the water to run until it is as cold as it will get (usually 2-3 minutes). Do not use water from the hot water tap for drinking or cooking because hot water dissolves lead in the plumbing system more quickly than cold water. For more information see the DNR publication *Lead in Drinking Water.*
- ✓ Replace lead pipes or copper pipes that have been soldered with lead.
- ✓ Avoid drinking water treated by a water softener. Soft water can be corrosive to pipes and allow lead to leach into the water. If water is naturally too soft, see "Corrective Action for Corrosivity" for steps to harden the water.

Chloride

In most areas of Wisconsin, chloride in groundwater is naturally less than 10 mg/l. Some higher concentrations in limestone and sandstone aquifers in eastern Wisconsin may also be natural. Higher concentrations usually indicate contamination by septic systems, road salt, fertilizer, animal or other wastes. Chloride is not toxic, but some people can detect a salty taste at 250 mg/l. Water with high



may also
have a high sodium content. High chloride may also speed up corrosion in plumbing (just as road salt does to your car).

ACCEPTABLE RESULTS: There is no health standard. Levels less than 10 mg/l are desirable. Levels more than 250 mg/l may cause a salty taste.

SOURCES: Septic systems, road salt, fertilizer, animal or other wastes.

CORRECTIVE ACTIONS: None required specifically for chloride. If elevated chloride levels are found in combination with high nitrate levels, take corrective actions indicated for nitrate.

Conductivity

Conductivity (specific conductance) is a measure of water's ability to conduct an electrical current. It is related to the amount of dissolved minerals in water, but it does not give an indication of which minerals are present. Conductivity (measured in µmho/cm at 25°C) is about twice the hardness (mg $CaCO_3$/l) in most

uncontaminated waters in Wisconsin. If it is much greater than two times the hardness, it may indicate the presence of contaminants such as sodium, chloride or sulfate, which may be influenced by humans or naturally-occurring. Changes in conductivity over time may indicate changing water quality.

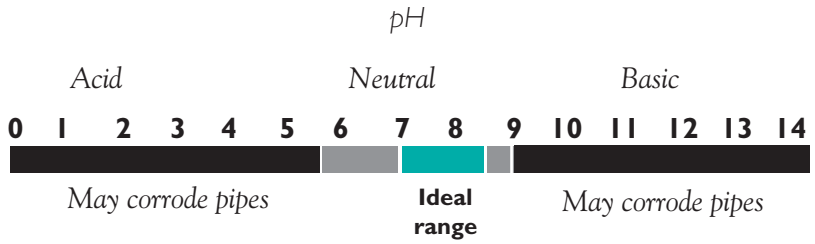
ACCEPTABLE RESULTS: There is no health standard. A normal conductivity value is roughly twice the hardness in unsoftened water.

SOURCES: Natural and synthetic dissolved substances in the water.

CORRECTIVE ACTIONS: None specifically required for conductivity.

pH

The measure of the hydrogen ion (acid) concentration in water is called pH. A pH of 7 is neutral. Values above 7 are alkaline or basic; those below 7 are acidic. A change of 1 pH unit is a tenfold



change in acid level. Acidic water is often corrosive (see Corrosivity Index). Iron may also be found at problem levels in acid water. Lab pH values are often slightly higher than would be found at your well.

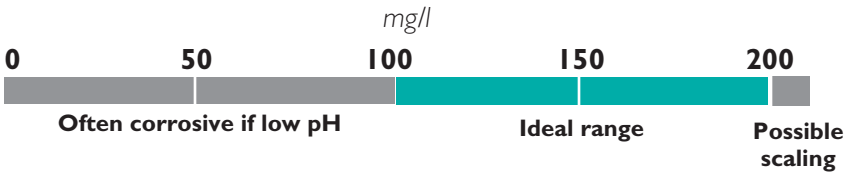
ACCEPTABLE RESULTS: There is no health standard. Values from 6.5 to 8.5 pH units occur in most natural waters. The lower the pH, the more corrosive the water will be.

SOURCES: Low values are most often caused by lack of carbonate minerals, such as calcium and magnesium found in limestone. Water leaking from a landfill may also lower pH.

CORRECTIVE ACTIONS: See Corrosivity Index.

Alkalinity

Alkalinity is a measure of water's ability to neutralize acids, and so is directly related to pH. It results primarily from carbonate minerals, such as those found in limestone, dissolving in the aquifer. Alkalinity and total hardness are usually nearly equal in concentration when both are reported in mg/l $CaCO_3$ (calcium carbonate), because they come from the same minerals. If alkalinity is much higher than total hardness in an unsoftened sample, consider testing for sodium. If alkalinity is much lower than total



hardness, test for chloride, nitrate and sulfate.

The lower the alkalinity, the more likely water is to be corrosive. Water with high alkalinity (greater than 150 mg/l) may cause scale (lime) buildup in plumbing.

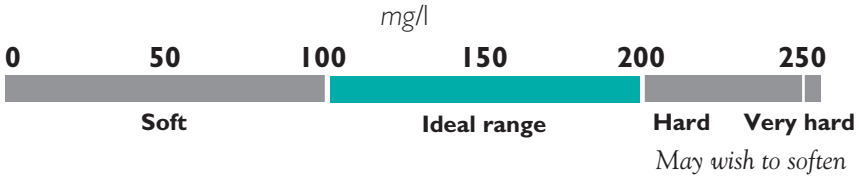
ACCEPTABLE RESULTS: There is no health standard. Values near 150 are considered ideal if the corrosivity index is satisfactory. When expressed as mg/l $CaCO_3$, the value should be near that of hardness (from 75 to 100 percent of the hardness value).

SOURCES: Primarily dissolved limestone minerals from soil and rock materials.

CORRECTIVE ACTIONS: See Corrosivity Index.

Hardness

Hardness in water is caused mostly by dissolved calcium and magnesium, the end product of dissolving limestone from soil and rock materials. Hard water is beneficial to health. However, high hardness can cause lime buildup (scaling) in pipes and water



heaters. It also reacts with soap to form a "scum" which decreases soap's cleaning ability, increases bathtub ring and turns white laundry grey. Water that is naturally too soft may be corrosive. The water softening industry measures hardness in grains per gallon. One grain/gallon=17.1 mg/l $CaCO_3$.

ACCEPTABLE RESULTS: Hard water is beneficial to health. However, values near 150 mg/l are ideal from an aesthetic viewpoint, if the corrosivity index is satisfactory.

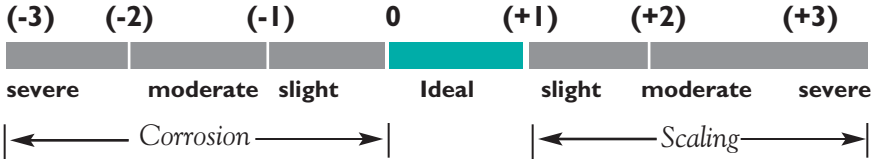
SOURCES: Primarily dissolved limestone minerals from soil and rock materials.

CORRECTIVE ACTIONS: See Corrosivity Index.

Corrosivity Index (also called Saturation Index, Stability Index, Langelier Index)

Corrosivity index is a measure of the tendency for lime (calcium carbonate) to precipitate (form and settle out) from water. It is calculated from pH, alkalinity, calcium hardness and conductivity data.

Water is a good solvent, and will attack unprotected metal plumbing. Lead, copper and zinc from pipes and solder joints may then leach (dissolve) into drinking water. Symptoms of corrosive



water include pinhole leaks in copper pipes or green stains on plumbing fixtures. Lime precipitate (scale) from hard water is a natural protection against corrosion. Too much scale, however, will partially plug pipes and water heaters, decreasing their efficiency. Water softeners prevent scale buildup, but they can also destroy any protection from corrosion the water may have provided.

ACCEPTABLE RESULTS: There is no health standard. Values between 0 and 0.5 units are considered the most desirable for a corrosivity index. However, the relationship between the corrosivity index and leaching of metals is imperfect. You may still need to test your water for lead, or run the water until cold before drinking it, if your plumbing contains lead.

SOURCES: Low values may be caused by natural lack of minerals in the aquifer and/or high nitrate levels. High values normally relate to high water hardness and alkalinity.

CORRECTIVE ACTIONS FOR CORROSIVITY, HARDNESS, ALKALINITY OR pH: If values are too low, indicating a corrosion problem, you should consider:

- ✓ Deepening the well.
- ✓ Increasing the hardness and/or alkalinity of the water with a water treatment device (see fact sheet G3558-5 *Choosing a Water Treatment Device*).

Should I Worry About Changes in My Water?

Sudden changes in water quality may be a sign of serious contamination problems which may harm health. If there is a problem with the construction of your private well, you are especially likely to observe sudden changes in taste, odor or clarity in the spring or after heavy rain. Such changes should be investigated immediately with laboratory testing for coliform bacteria and nitrate. The water may be used for washing and bathing but should not be consumed until the laboratory results show that your water is safe.

You may find that some changes you observe are natural. If your water quality changes routinely at a certain time of year, you may want to make that the time at which you do your routine annual testing. Ultimately, sampling frequency is a personal decision which should be based on personal judgment, level of concern, and previous contamination levels.

- ✓ Running water for several minutes before using it for drinking or cooking if the plumbing includes lead pipes or lead solder. Replacing all plumbing with plastic would be also be a solution.

If values are too high, indicating a scaling problem:

- ✓ Soften water (except a cold water tap for drinking water).

When You Should Consider Additional Tests

In addition to the initial set of tests, and once-a-year checks for bacteria and nitrate, you should consider additional testing of your private water supply in the following circumstances:

If you are installing a water treatment device
TEST FOR: Any contaminants you are concerned about removing. You will need to know the levels of contaminants present to choose the best treatment device.

If you have copper pipes soldered with lead solder or lead pipes
TEST FOR: Lead.

If there is an infant in the home
TEST FOR: Nitrate and bacteria before the infant begins drinking the water.

If there is a family illness that could be related to drinking water (such as gastrointestinal illness)
TEST FOR: Bacteria. (Consult a physician for medical advice.)

If there are noticeable changes in livestock or poultry performance
TEST FOR: Compounds measured in the initial water test.

If your neighbors find one or more contaminants when they test their well
TEST FOR: The same contaminants found in the neighbors' well.

If agricultural chemicals or petroleum products have been spilled near your well, or you suspect an accident might have back-siphoned these products into the well
TEST FOR: The volatile organic chemicals (VOCs) or suspected pesticides.

If pesticides or fertilizers are applied to fields within 100 feet of your well
TEST FOR: Nitrate and pesticides with a scan that includes the pesticides used on the fields. If corn is grown, consider screening for atrazine, a common corn herbicide.

If there is an old underground fuel storage tank nearby
TEST FOR: Oil, gasoline and volatile organic chemicals.

If indoor air testing reveals radon concentrations higher than 4 picocuries/liter in kitchen and bathroom areas (Radon is a naturally-occurring radioactive substance in geological materials in some areas; in well water, radon can contribute to elevated

indoor air radon levels.)
TEST FOR: Radon. Contact the DNR water supply specialist for help.

If you notice rust stains on bathroom or kitchen fixtures, laundered clothes, cooking utensils
TEST FOR: Iron.
